Input and output variables

The **input variables**¹ are typically denoted using the symbol X. If we observe p different variables, we write $X = (X_1, X_2, \dots, X_p)$. The inputs belong to an *input space* \mathcal{X} .

• Examples: $\mathcal{X} \subseteq \mathbb{R}^p$ or $\mathcal{X} = \{0,1\}^p$.

The **output variable**² is typically denoted using the symbol Y. The output belongs to an *output space* \mathcal{Y} .

- Regression: $\mathcal{Y} \subseteq \mathbb{R}$
- Classification (with K categories): $\mathcal{Y} = \{C_1, C_2, \dots, C_K\}$
 - Binary classification (K = 2): $\mathcal{Y} = \{-1, 1\}$ or $\mathcal{Y} = \{0, 1\}$

¹also called *predictors*, *independent variables*, *features*, *variables* or just *inputs*.

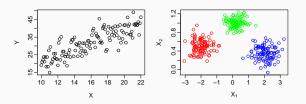

²also called the *response* or *dependent variable*.

The dataset

The **dataset**, also called *training set*, is a set of n input-output pairs, given by

$$\mathcal{D} = \{(x_1, y_1), (x_2, y_2), \dots, (x_n, y_n)\} = \{(x_i, y_i)\}_{i=1}^n.$$

Each pair, also called an *example* or a *data point*, belongs to the *data space* $\mathcal{X} \times \mathcal{Y}$.

- Left figure: $\mathcal{X} \subseteq \mathbb{R} \ (p=1)$ and $\mathcal{Y} \subseteq \mathbb{R}$
- Right figure: $\mathcal{X} = \mathbb{R}^2 \ (p = 2)$ and $\mathcal{Y} = \{R, G, B\}$

Data distribution

We assume the data points (x_i, y_i) are i.i.d. realizations from a fixed <u>unknown</u> data distribution $p_{X,Y}$, which represents different sources of uncertainty. In other words, we have $(X, Y) \sim p_{X,Y}$.

The probability distribution $p_{X,Y}$ can be factorized as

$$p_{X,Y}(x,y) = p_X(x)p_{Y|X}(y|x),$$

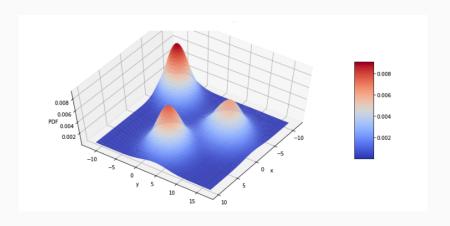

where

- the marginal distribution p_X models uncertainty in the sampling of the inputs.
- the conditional distribution p_{Y|X} describes a stochastic (non-deterministic) relation between inputs and output.

Equivalently, we have

$$X \sim p_X$$
 and $Y|X = x \sim p_{Y|X}(\cdot|x)$.

Data distribution

The loss function

Given a prediction $\hat{y} \in \mathcal{Y}$ and the true (observed) value $y \in \mathcal{Y}$, the **loss function**

$$L: \mathcal{Y} \times \mathcal{Y} \to [0, \infty),$$

measures how far \hat{y} is from y.

In the continuous case, examples include the squared error loss

$$L(y, \hat{y}) = (y - \hat{y})^2,$$

and the absolute error loss

$$L(y, \hat{y}) = |y - \hat{y}|.$$

In the discrete case, an example is the zero-one loss

$$L(y,\hat{y}) = \mathbb{1}\{y \neq \hat{y}\},\$$

where $\mathbb{1}\{\}$ is the indicator function.

Let us consider a **hypothesis** ("prediction function")

$$h: \mathcal{X} \to \mathcal{Y}$$
.

Let us consider a **hypothesis** ("prediction function")

$$h: \mathcal{X} \to \mathcal{Y}$$
.

We define the **out-of-sample error**³ of h as

$$E_{\text{out}}(h) = \mathbb{E}_{x,y}[L(y,h(x))] = \mathbb{E}_x \left[\underbrace{\mathbb{E}_{y|x}[L(y,h(x))|x]}_{E_{\text{out}}(h,x)} \right]$$
(1)

The **optimal prediction function** is given by

$$f = \underset{h:\mathcal{X} \to \mathcal{Y}}{\operatorname{argmin}} E_{\operatorname{out}}(h).$$

³also called **expected error** or **expected risk**.

$$f = \underset{h: \mathcal{X} \to \mathcal{Y}}{\operatorname{argmin}} \ \mathbb{E}_{x,y}[L(y, h(x))] := E_{\text{out}}(h).$$

- 1. We do not know $p_{X,Y}$
- 2. We search among all functions $h: \mathcal{X} \to \mathcal{Y}$

Let \mathcal{H} be a **hypothesis set**, i.e. a set of prediction function (hypotheses) under consideration.

Given a dataset $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^n$ where $(x_i, y_i) \stackrel{\text{i.i.d.}}{\sim} p_{X,Y}$, we can solve the following optimization problem:

$$g (= g_{\mathcal{D}}) = \underset{h \in \mathcal{H}}{\operatorname{argmin}} \frac{1}{n} \sum_{i=1}^{n} L(y_i, h(x_i)) := E_{\operatorname{in}}(h),$$

where E_{in} is the in-sample error or training error.

Compare it with

$$f = \underset{h: \mathcal{X} \to \mathcal{Y}}{\operatorname{argmin}} \ \mathbb{E}_{x,y}[L(y, h(x))] := E_{\text{out}}(h).$$

Summary

The **dataset** $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^n$ is composed of n input-output pairs (x_i, y_i) , which are i.i.d. realizations from the **data distribution** $p_{X,Y}$ where $X \in \mathcal{X}$ and $Y \in \mathcal{Y}$.

The loss function $L: \mathcal{Y} \times \mathcal{Y} \to [0, \infty)$ allows us to measure the error we incur in predicting \hat{y} in place of y.

The **hypothesis set** \mathcal{H} is a set of prediction function under consideration. Each hypothesis $h \in \mathcal{H}$ has an **in-sample error** $E_{\text{in}}(h)$, computed using \mathcal{D} , and an **out-of-sample error** $E_{\text{out}}(h)$, which depends on $p_{X,Y}$.

Given $\mathcal H$ and using $\mathcal D$, the **learning algorithm** $\mathcal A$ picks the best hypothesis g from $\mathcal H$ according to the loss function $\mathsf L$.

Together, the hypothesis set and the learning algorithm are referred to as the **learning model**.

Linear models

Linear models

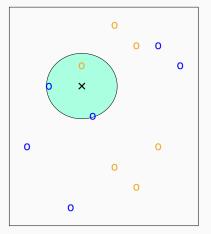

Let us consider a regression problem where $x \in \mathbb{R}^p$.

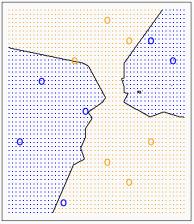

• The hypothesis set for linear models is given by

$$\mathcal{H} = \{ h(x) = \beta_0 + \beta_1 x_1 + \dots + \beta_p x_p : \beta_0, \beta_1, \dots, \beta_p \in \mathbb{R} \}$$

 One learning algorithm is the (ordinary) least squares method.

K-Nearest Neighbours model

K-Nearest Neighbours (KNN) is one of the simplest machine learning model for both classification and regression.

K-Nearest Neighbours model

Given a dataset $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^n$, the number of neighbors $K \leq n$,, and a new input x_* :

- (1) Find the K nearest points to x_* in \mathcal{D} , denoted \mathcal{N}_* .
 - Classification with M categories (y ∈ {C₁,..., C_M})
 (2)

$$\hat{p}(C_m \mid x = x_*) \approx \frac{1}{K} \sum_{i \in \mathcal{N}_*} \mathbb{1}\{y_i = C_m\} \quad (m = 1, 2, ..., M)$$

$$h(x_*) = C_{m^*}$$
 where $m^* = \operatorname{argmax}_m \hat{p}(y = C_m \mid x = x_*)$

Regression(2)

$$h(x_*) = \frac{1}{K} \sum_{i \in \mathcal{N}} y_i$$

Parametric and non-parametric models

- In a parametric model, every hypothesis is uniquely defined by a fixed number of parameters.
- In a non-parametric model, we can not describe a hypothesis with a fixed number of parameters. Usually the number of "parameters" grows with the size of the dataset.
- Both parametric and non-parametric models have hyper-parameters (structural parameters), while parametric models also have parameters
 - For KNN, K is a hyper-parameter.
 - For linear models, p is a hyper-parameter, and the coefficients β_j are parameters.
- We also make a distinction between linear and non-linear models.

Estimation of the out-of-sample error with resampling methods

$E_{\rm in}$ for MLE

Recall that, given a set of possible distributions

$$\mathcal{H} = \{ p(y; \boldsymbol{\theta}) : \boldsymbol{\theta} \in \boldsymbol{\Theta} \},$$

the maximum likelihood estimator is given by

$$\hat{\theta} = \underset{\theta \in \Theta}{\operatorname{argmax}} \sum_{i=1}^{n} \log p(y_i; \theta) = \underset{\theta \in \Theta}{\operatorname{argmin}} \underbrace{\frac{1}{n} \sum_{i=1}^{n} -\log p(y_i; \theta)}_{E_{\text{in}}(\theta)}. (2)$$

Since each hypothesis h is completely characterized by θ , this is equivalent to

$$g = \underset{h \in \mathcal{H}}{\operatorname{argmin}} E_{\operatorname{in}}(h).$$

E_{out} for MLE

By (strong) law of large numbers,

$$\frac{1}{n}\sum_{i=1}^{n}-\log p(y_i;\theta)\stackrel{n\to\infty}{\longrightarrow} \mathbb{E}[-\log p(y;\theta)]$$

In other words, we can think of maximum likelihood estimation as trying to minimize

$$E_{\text{out}}(\theta) = \mathbb{E}[-\log p(y; \theta)]$$

E_{out} for MLE

$$\underset{\theta \in \Theta}{\operatorname{argmin}} \ E_{\operatorname{out}}(\theta) = \underset{\theta \in \Theta}{\operatorname{argmin}} \ \mathbb{E}[-\log \ p(y; \theta)] \tag{3}$$

$$= \underset{\theta \in \Theta}{\operatorname{argmin}} \mathbb{E} \left[\log p(y) - \log p(y; \theta) \right] \tag{4}$$

$$= \underset{\theta \in \Theta}{\operatorname{argmin}} \mathbb{E} \left[\log \frac{p(y)}{p(y;\theta)} \right]$$
 (5)

$$= \underset{\theta \in \Theta}{\operatorname{argmin}} \int \log \frac{p(y)}{p(y;\theta)} p(y) \, dy \tag{6}$$

$$= \underset{\theta \in \Theta}{\operatorname{argmin}} \ \mathsf{KL}(p_{\theta}, p), \tag{7}$$

where KL(q, p) is the KL-divergence between two distributions q and p, which measures the discrepancy between the two distributions. Note that KL-divergence is not a distance measure (not symmetric).

Estimation of the out-of-sample error with resampling methods

Training and test errors

Consider

$$f = \underset{h: \mathcal{X} \to \mathcal{Y}}{\operatorname{argmin}} E_{\operatorname{out}}(h),$$

$$g^* = \underset{h \in \mathcal{H}}{\operatorname{argmin}} \ E_{\operatorname{out}}(h),$$

and

$$g = \underset{h \in \mathcal{H}}{\operatorname{argmin}} E_{\operatorname{in}}(h).$$

How different are $E_{out}(g)$ and $E_{out}(f)$?

The approximation-generalization tradeoff

The difference between the out-of-sample error of g and f can be decomposed as follows

$$E_{\mathrm{out}}(g) - E_{\mathrm{out}}(f) = \underbrace{\left[E_{\mathrm{out}}(g^*) - E_{\mathrm{out}}(f)\right]}_{\text{Approximation error}} + \underbrace{\left[E_{\mathrm{out}}(g) - E_{\mathrm{out}}(g^*)\right]}_{\text{Estimation error}}$$

- Approximation error is how far the entire hypothesis set is from f. Larger hypothesis sets have lower approximation error.
- **Estimation error** is how good *g* is with respect to the best in the hypothesis set. Larger hypothesis sets have higher estimation error because it is harder to find a good prediction function based on limited data.

This is called the **approximation-generalization** tradeoff.

How does E_{out} relates to E_{in} ?

$$E_{\text{out}}(g) = E_{\text{in}}(g) + [E_{\text{out}}(g) - E_{\text{in}}(g)].$$

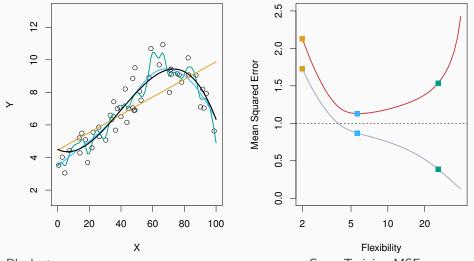

To obtain a small $E_{out}(g)$, we want

- 1. small $E_{in}(g)$
- 2. small $[E_{out}(g) E_{in}(g)]$

In the following, we will see that the selection of the best hypothesis g by minimizing $E_{\text{in}}(g)$ can be misleading. Let $\mathcal{D}' = \{(x_i', y_i')\}_{i=1}^n$ be another sample (independent of \mathcal{D}) where $(x_i', y_i') \overset{\text{i.i.d.}}{\sim} p_{X,Y}$. We define the **testing/test error** as

$$E_{\text{test}}(g) = \frac{1}{n'} \sum_{i=1}^{n'} L(y_i', g(x_i')).$$

Training and test errors

Model selection and assessment

Estimation of the out-of-sample error with resampling methods

The model selection problem

- How many and which input variables should we choose?
- How do we choose the number of neighbours K in KNN?
- ..
- More generally, how do we choose the hyper-parameters of a machine learning model?
- ightarrow We need a way of **assessing** and **selecting** the best model among multiple competing models.

The model selection/structural identification procedure

1. Model generation

Generate a set of candidate model structures among which the best one is to be selected. If applicable, estimate the parameters of each candidate model, i.e. fit the model by minimizing the in-sample (training) error (parametric identification).

2. Model assessment/validation

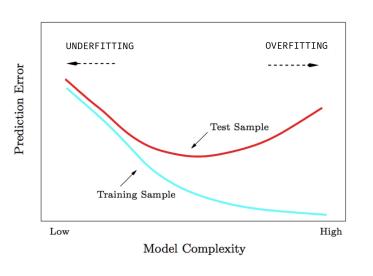

Evaluate/validate the model's performance by computing a validation error, i.e. an estimate of the out-of-sample error.

3. Model selection

Select the final model structure in the set that has been proposed by **model generation** and assessed by **model validation**. We typically select the model structure that minimizes the validation error.

35

Why not use the in-sample (training) error for model selection?

How to estimate the out-of-sample error?

$$E_{\mathrm{out}}(h) = E_{\mathrm{in}}(h) + \underbrace{\left[E_{\mathrm{out}}(h) - E_{\mathrm{in}}(h)\right]}_{\mathrm{overfit\ penalty}}, \quad h \in \mathcal{H}.$$

- Directly estimate it using resampling methods, i.e. by resampling the data set. Examples include the validation set, cross-validation and bootstrap.
- Estimate the overfiit penalty and add it to the in-sample (training) error.

Model selection and assessment

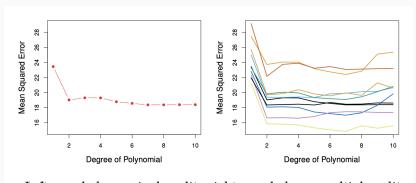

Estimation of the out-of-sample error with resampling methods

Validation-set approach

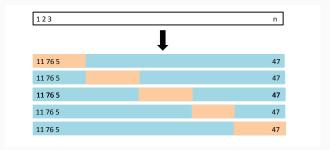

- We randomly divide the dataset into two parts: a training set and a validation set.
- The model is fit on the training set, and the fitted model is used to predict the responses for the observations in the validation set
- The resulting validation-set error provides an estimate of the out-of-sample error.
- This estimate of the out-of-sample error can be highly variable, depending on precisely which observations are included in the training set and the validation set.

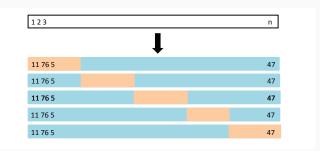

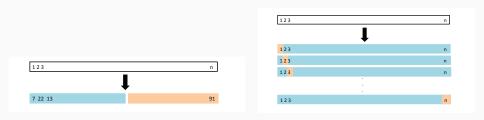

Validation-set approach

 $Left\ panel\ shows\ single\ split;\ right\ panel\ shows\ multiple\ splits$

- Divide the data set into *K* different parts.
- Remove one part, fit the model on the remaining K-1 parts, and compute the prediction error on the omitted part.
- Repeat K times taking out a different part each time
- By averaging the K prediction errors we obtain an estimate of the out-of-sample error, i.e. the prediction error for new observations (not used in training).
- Setting K = n yields n-fold or leave-one out cross-validation (LOOCV).

Let the K parts be A_1, A_2, \ldots, A_K , where A_k denotes the indices of the observations in part k. There are n_k observations in part k: if N is a multiple of K, then $n_k = n/K$.

Compute

$$CV = \sum_{k=1}^{K} \frac{n_k}{n} Err_k$$

where, for example,

$$\operatorname{Err}_{k} = \sum_{i \in A_{k}} \frac{1}{n_{k}} (y_{i} - \hat{y}_{i}^{(-k)})^{2} \text{ (squared error loss)},$$

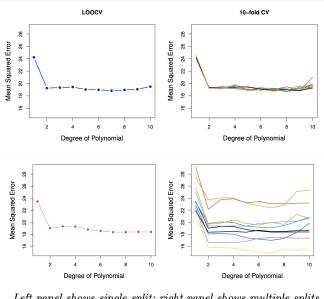

or

$$\operatorname{Err}_{k} = \sum_{i \in A_{k}} \frac{1}{n_{k}} \mathbb{1}\{y_{i} \neq \hat{y}_{i}^{(-k)}\} \text{ (zero-one loss)},$$

and $\hat{y}_i^{(-k)}$ is the prediction for observation i, obtained from the model fit with data where part k is removed.

K-fold Cross-validation - Bias and variance tradeoff

- Each training set is only (K-1)/K as big as the original data set. So the estimates of prediction error will be biased upwards.
- Bias minimized when K = n (LOOCV).
- But variance increases with K since the estimates from each fold are more correlated (as there are more overlapping observations in each part) and hence their average can have higher variance.
- Empiricial observation: K = 5 or K = 10 provide a good compromise for this bias-variance tradeoff.

Left panel shows single split; right panel shows multiple splits

For K-fold cross-validation, it's very helpful to assign a quantitative notion of variability to the cross-validation error estimate.

Assuming $n_k = n/K$, we can write

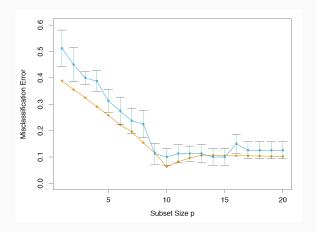

$$\mathsf{Var}(\mathit{CV}) = \mathsf{Var}\left(\sum_{k=1}^K \frac{1}{K} \mathsf{Err}_k\right) \approx \frac{1}{K^2} \sum_{k=1}^K \mathsf{Var}(\mathsf{Err}_1) = \frac{1}{K} \mathsf{Var}(\mathsf{Err}_1)$$

- This is an approximation since Err₁,..., Err_K are not i.i.d.
- This approximation is valid for small K (e.g., K = 5 or 10) but not really for big K (e.g., K = n), because then the quantities Err_1, \ldots, Err_K are highly correlated.
- We can compute the standard deviation or standard error of the cross-validation error estimate as

$$\frac{1}{\sqrt{K}}\mathsf{sd}\{\mathsf{Err}_1,\mathsf{Err}_2,\ldots,\mathsf{Err}_K\},$$

where sd denotes the empirical standard deviation.

The one standard error rule

Choose the simplest model whose CV error is no more than one standard error above the model with the lowest CV error

Cross-validation: right and wrong

Consider a simple regression procedure applied to a dataset with 500 predictors and 50 samples:

- 1. Find the 5 predictors having the largest correlation with the response
- 2. Apply linear regression using only these 5 predictors

How to use cross-validation to estimate the out-of-sample error of this procedure?

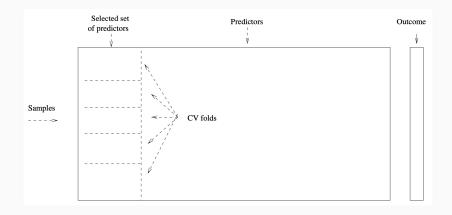

Cross-validation: right and wrong

Consider a simple regression procedure applied to a dataset with 500 predictors and 50 samples:

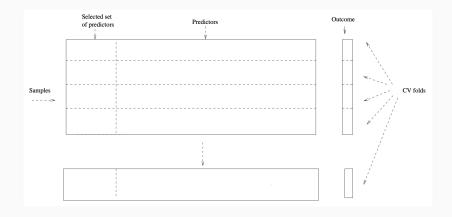

- 1. Find the 5 predictors having the largest correlation with the response
- 2. Apply linear regression using only these 5 predictors

How to use cross-validation to estimate the out-of-sample error of this procedure?

Wrong way

Right way

Cross-validation: right and wrong

Apply cross-validation to steps 1 and 2 (not just step 2)

→ Every aspect of the procedure that involves using the data — variable selection, scaling, etc — must be cross-validated.
